Conflict of Interest Statement

The Centre for Gambling Research at UBC receives funding from the Province of British Columbia and the British Columbia Lottery Corporation (BCLC), a Canadian Crown Corporation. The slot machine used in the present study was provided by the BCLC. The British Columbia Government and BCLC had no further involvement in the research design, methodology, conduct, analysis or write-up of the study, and impose no constraints on publishing.

LC is the Director of the Centre for Gambling Research at UBC. LC has received speaker/travel honoraria from Svenska Spel (Sweden), the National Association of Gambling Studies (Australia), and the National Center for Responsible Gaming (USA). He has received consulting fees from Gambling Research Exchange Ontario (Canada) and the National Center for Responsible Gaming (USA). He has not received any further direct or indirect payments from the gambling industry or groups substantially funded by gambling. He has received royalties from Cambridge Cognition Ltd. relating to neurocognitive testing.

MVC has received a speaker honorarium from the Responsible Gaming Association of New Mexico (USA).

EHLO works as a postdoctoral fellow at the Centre for Gambling Research. She has received a speaker honorarium from the Massachusetts Council on Compulsive Gambling
(USA). She has accepted travel or accommodation for speaking engagements from the National Council for Responsible Gambling (USA), the International Multidisciplinary Symposium on Gambling Addiction (Switzerland), and the Responsible Gambling Council (Canada). She has not received any further direct or indirect payments from the gambling industry or groups substantially funded by gambling.

WSM and MAF hold graduate fellowships from the Natural Sciences and Engineering Research Council of Canada (NSERC). LC holds an NSERC Discovery Grant. MS holds an NSERC Discovery Grant and NSERC Accelerator Supplement, and a Canada Foundation for Innovation grant that funded the mobile eye-tracking device.

KIM, and JF report no conflicts of interest.

Abstract

Background and Aims

Immersion during slot machine gambling has been linked to disordered gambling. Current conceptualizations of immersion (namely dissociation, flow, and the machine zone) make contrasting predictions as to whether gamblers are captivated by the game per se (‘zoned in’) or motivated by the escape that immersion provides (‘zoned out’). We examined whether selected eye movement metrics can distinguish between these predictions.

Design and Setting

Pre-registered, correlational analysis in a laboratory setting. Participants gambled on a genuine slot machine for 20 minutes while wearing eye tracking glasses.

Participants

Fifty-three adult slot machine gamblers who were not high-risk problem gamblers.

Measurements

We examined self-reported immersion during the gambling session and eye movements at different areas of the slot machine screen (the reels, the credit window, etc.). We further explored these variables’ relationships with saccade count and amplitude.

Findings

The ratio of dwell time on the game’s credit window relative to the game’s reels was positively associated with immersion ($t(51) = 1.68, p = .049$ one-tailed, $R^2 = .05$). Follow-up analyses described event-related changes in these patterns following different spin outcomes.

Conclusions

Immersion while gambling on a slot machine appears to be associated with active scanning of the game and a focus on the game’s credit window. These results are more consistent with a ‘zoned in’ account of immersion aligned with flow theory than a ‘zoned out’ account based on escape.
Introduction

Immersion is a feeling of intense focus on a particular activity that reduces attention to competing goals and stimuli. Although viewed as desirable in many occupational and recreational contexts (1), immersion in gambling activities is a robust predictor of problem gambling risk (2–10). Slot machine gambling may be especially immersive: an Australian survey found that 79% of gambling-related immersion experiences involved slot machines (11).

Recently, authors have called for clarity in defining slot machine immersion (12). Previous work has characterized this state as ‘dissociation’, (3,9,13–16), the ‘machine zone’ (17,18), or ‘flow’ (5,19). These accounts all highlight a trance-like state that interferes with gamblers’ awareness of peripheral events (e.g. people talking nearby) and the passage of time. However, the machine zone and dissociation (15,18) constructs differ from flow by relying on a negative reinforcement mechanism: a sense of relief or escape from aversive realities that is provided by slot machines. Schull (21 p. 2, 74) argues that immersion supplants the desire to win money, becoming the sole motivation for gambling. By this account, gamblers could be relatively passive or ‘zoned out’ while gambling, showing little engagement with the game per se. In contrast, the flow account implies that these experiences emerge from skilful performance commensurate to the challenge or difficulty of the task (1). This implies a ‘zoned in’ state in which task attention must be maintained to stay in the immersive ‘flow channel’ (1). By this account, gambling success necessarily remains a valued goal, the pursuit of which generates immersion.

Most research on slot machine immersion has employed self-report measures, but a few behavioural studies tested whether immersed gamblers were less responsive to stimuli outside the game (3,4,7). Crucially, this ‘dual task’ approach cannot assess the allocation of attentional resources to the game itself. Mobile eye tracking technology offers a means of exploring aspects of overt visual attention during gambling. Rogers and colleagues (2017) used mobile eye tracking to examine betting behaviour on fixed-odds betting terminals in British gambling shops, finding that problem gamblers spent more time looking at ‘amount-won’ messages. This finding complements laboratory studies in which people with gambling problems show visual biases towards gambling-related imagery (21,22).

Our primary aim was to ascertain whether slot machine immersion is akin to being ‘zoned in’ or ‘zoned out’. These characterizations lead to testable and competing predictions regarding eye movements during the immersed state. If gamblers are ‘zoned in’, they should be relatively more attentive and reactive to the slot machine display – especially to financial information displayed in the credit window, as the main indicator of ‘performance’ (albeit in a game of chance). If they are ‘zoned out’, gamblers should be relatively less attentive to their task performance, instead directing their eyes to the most stimulating parts of the display: the spinning reels.

We pre-registered1 several hypotheses (based on a convenience-sampled pilot study, see Supplementary Materials S1), to arbitrate between these accounts using eye movement metrics during slot machine gambling (Table 1). We hypothesized that immersed gamblers would look

---

1 Pre-registration: https://aspredicted.org/k4ty9.pdf
relatively more at the game’s credit window and relatively less at the reels in a slot machine gambling session. We interpret this behaviour as consistent with being ‘zoned in’.

We examined whether immersed gamblers make more saccades and fewer blinks. We believe such results would be consistent with being ‘zoned in’, while the opposite pattern would indicate being ‘zoned out’. Exploring these data further, we examined event-related fixations during different phases within each bet. We looked for relationships between slot machine outcomes and immersion. Lastly, we examined whether immersion was related to gambling-related cognitions, negative affect (5), or symptoms of adult Attention Deficit Hyperactivity Disorder (ADHD; 23–25; see Supplementary Materials S3) that have correlated with immersion in past research.

Methods

Participants

Experienced slot machine gamblers were recruited through craigslist.ca. Respondents (N = 245) completed an online eligibility screening. We recruited respondents age 19 or older, who reported slot machine use (including online) in the past 12 months, and who reported normal vision, using contact lenses, or using glasses with a prescription strength between -4 and +4 diopters. We excluded respondents who reported recent or severe traumatic brain injury, neuropsychiatric or ophthalmic disease, or current use of psychotropic medications. Because the experiment involved authentic slot machine gambling, we excluded individuals who scored 8 or higher on the Problem Gambling Severity Index (26).

Participants (N = 63) were paid $20 CAD for attending a 1-hour test session, and received $0-20 as an additional bonus from the slot machine. Ten participants were excluded from analysis: seven due to poor quality eye tracking data, one due to a video capture error that made behavioural data unavailable, and two who reported past-year slot machine use on the eligibility screen but none on test day. All experimental protocols were approved by UBC’s research ethics board.

Questionnaires

After providing written consent, participants completed four questionnaires (see Supplementary Materials S2): the Short-Form Adult ADHD Self-Report Scale (27), the Gambling-Related Cognitions Scale (GRCS; 25), the Depression, Anxiety and Stress Scale (29), and the Problem Gambling Severity Index (PGSI; 23).

Following the slot machine task, participants completed an immersion questionnaire, which is a concatenation of the Dissociation Questionnaire (3,16) and Flow subscale of the Game Experience Questionnaire (30,31). Seven items (e.g. “I lost track of time while playing the slot machine,” “I felt completely absorbed,”) were rated on a 5-point Likert scale ranging from “Very
slightly or not at all (0)” to “Extremely (4)”. Mean scores were calculated and reliability analyses were performed. We have previously employed this measure (25).

Procedure

Participants gambled on a real slot machine for up to 20 minutes using a $40 endowment. We recorded natural gaze behaviour in real time using mobile eye tracking glasses (SMI, Teltow, Germany). For additional detail, see Supplementary Materials S2.

Data Processing

Binocular eye position data were pre-processed using proprietary software (SMI BeGaze 3.7). Data were mapped to a reference image based on the screen layout of the slot machine (Figure 1). Six mutually-exclusive areas-of-interest (AOIs) were defined on the reference image: 1) reels, 2) credit window, 3) win window (a larger window to the right of the credit window that reads zero unless a payout is being delivered), 4) menu bar (which displays information about the game denomination, and bet size), 5) game border (the remaining screen area not included in other AOIs), and 6) game periphery (the entire area outside the game screen). Session-wise statistics were exported from BeGaze alongside the raw reference image data. Blinks and saccades were defined automatically in BeGaze. Saccade amplitude was defined as the average distance (pixels) between the start and end position of all saccades. Dwell time was defined as the percentage of task time spent fixating on a given AOI. Fixations were defined as the number of times visual intake was recorded in an AOI following a blink or saccade, divided by task time. Gaze data normalized by AOI size are presented in Table 2 for descriptive purposes. Analyses were performed on the non-normalized data. The ratio of dwell time (or fixations) at the credit window to the reels was calculated (see Supplementary Materials S1). Data were analyzed in R (32–36). Descriptive data are reported with median, minimum, and maximum values where skew was present. Non-event-related hypotheses were tested using bivariate regression. Reported confidence intervals were bootstrapped with 5,000 iterations (37).

Event-Related Analyses

To further explore whether fixation patterns might be affected by specific in-game events and immersion, we derived a time series of on-screen game events for trial-by-trial analyses. We analyzed data at three phases within each trial: reel spin, audiovisual feedback (where reinforcement is delivered paired with some sound and animation), and spin initiation latency (the delay between the feedback ending and the participant initiating the next spin, Figure 2). Spin outcomes were categorized into wins, losses, free spin bonuses, and losses-disguised-as-wins (38). Of these, loss trials are unique in entailing a spin initiation latency phase with no preceding feedback phase, since no credits are awarded. The music and spins in a free spin bonus continue without pausing for user input, so we treated them as a single feedback phase. Our use of a genuine slot machine meant that we could not control how many outcomes of each type
occurred, or the order in which they appeared. In total, 20,749 events were recorded for each model.

**INSERT FIGURE 2 NEAR HERE**

For each trial phase, we recorded a trial number, duration (seconds), outcome type (loss, win, losses-disguised-as-wins or free spin bonus; reel spins were the reference category), and the proportion of that phase spent fixating on the reels, credit window and win window. Data inspection showed that many phases were spent fixating on only one AOI, polarizing the data (i.e. one AOI value equalled one, and the rest zero). To address this, all non-zero event-related eye movement data were converted to 1 and data were analyzed in three fixed-effects logistic regressions (39–41) that tested the likelihood the reels, credit window or win window were fixated-on during a given phase (additional details in Supplementary Materials S2).

Models were composed first of participant (fixed factor), trial number (centered at one), and phase duration (grand-mean centered). These factors accounted for incidental variance between participants, across the span of the task, and as a result of some outcomes (e.g. bonus features) being systematically longer in duration. We then added the dummy-coded outcome phases. Predictions made by these models thus reflect differences in the likelihood of fixating on a given AOI during a particular outcome phase, compared to when the reels are spinning. Lastly, for outcome phases that significantly differed from reel spins, immersion was tested as an interaction term. Non-significant interaction terms were backwards-eliminated, increasing these exploratory models’ parsimony and statistical power, but also the risk of type 1 error. Bootstrapping these data produced instances of complete separation, so not all confidence intervals in Table 3 were bootstrapped.

**Results**

After data cleaning, the final sample included 53 participants (84.13%, 32 males, 21 females) with a median age of 30 (range = 19 – 64). Most participants (n = 34, 64.15%) reported casino gambling one to five times in the past year. Seventeen (32.08%) reported visiting casinos more than five times. Two (3.77%) reported gambling on slot machines online, but not in a casino. The modal (n = 23, 43.40%) PGSI score was 0; 17 (32.10%) scored 1 - 2 (low-risk), and 13 (24.53%) scored 3 - 7 (moderate-risk).

The median participant made 179 spins (range = 117 – 233) during the task. Losses were the most common outcome (median = 140, range = 95 – 190). Losses-disguised-as-wins (median = 18, range = 10 – 33) occurred about as often as wins (median = 17, range = 8 – 28). The median participant saw one free spin bonus round (range = 0 – 4), and 14 participants (26.32%) did not experience any of the 58 bonuses that occurred. Sixteen participants (30.19%) finished the session in profit, and the median participant finished the task with $17.20 (range = $0 – $109.40) of their $40 endowment remaining. Among the 18 participants (33.96%) who ran out of credit before completing a 20-minute session, the median session length was 16.28 minutes (range = 11.00 – 20.00).
The reels AOI accounted for the most dwell time (mean = 71.46%, SD = 10.06), but participants also dwelt on the credit window (mean = 4.45%, SD = 2.98) and win window (mean = 3.07%, SD = 1.72). Only 0.97% (SD = 1.97) of dwell time occurred off screen (see Table 2 and Figure 3). When these values were normalized to account for the size of each AOI, a clear bias towards the credit window was observed.

Exploratory Hypotheses

Cronbach’s alpha for the immersion questionnaire was .75, an improvement over the Dissociation Questionnaire alone (.60). The median immersion score was 1.14 out of 4 (range = 0.14 – 2.86). Immersion was significantly related to PGSI ($\beta = 1.02$, $t(51) = 2.62$, $p = .012$, $R^2 = .12$, 95% CI [0.16, 1.77]), as well as several GRCS subscales. Among them, the subscales for illusion of control ($\beta = 0.73$, $t(50) = 3.18$, $p = .003$, $R^2_{\text{partial}} = .17$, 95% CI [0.30, 1.23], PGSI included as a covariate) and predictive control ($\beta = 0.65$, $t(50) = 2.47$, $p = .017$, $R^2_{\text{partial}} = .11$, 95% CI [0.10, 1.20]; additional results in Supplementary Materials S3).

The median participant blinked 6.92 times per minute (range = 0.35 – 52.66) and made 147.57 saccades per minute (range = 86.04 – 186.72). Immersion was associated with a greater total number of saccades during the slot machine task ($\beta = 13.40$, $t(51) = 2.95$, $p = .005$, $R^2 = .15$, 95% CI [5.17, 21.15], Figure 4A). The number of saccades was not related to saccade amplitude ($\beta = -.08$, $t(51) = -0.49$, $p = .629$, $R^2 < .01$, 95% CI [-0.38, 0.29]). Additional results are discussed in Supplementary Materials S3.

Pre-Registered Primary Hypotheses

The pre-registered hypotheses were partially supported. Consistent with our pilot results (see Supplementary Materials S1), a higher ratio of dwell time to the credit window AOI relative to the reels AOI was associated with higher levels of self-reported immersion during the slot machine task ($\beta = 2.98$, $t(51) = 1.68$, $p = .049$ one-tailed, $R^2 = .05$, 95% CI$_{\text{lower}} = 0.59$, Figure 4B). The overall number of fixations on the different AOIs (credit window/reels) was not related to higher immersion ($\beta = 2.39$, $t(50) = 1.23$, $p = .112$ one-tailed, $R^2 = .03$, 95% CI$_{\text{lower}} = -0.59$). Neither dwell time ratio ($\beta = 0.30$, $t(50) = 0.06$, $p = .478$ one-tailed, $R^2 < .01$, 95% CI$_{\text{lower}} = -7.69$), nor fixation ratio ($\beta = -0.35$, $t(50) = -0.06$, $p = .476$ one-tailed, $R^2 < .01$, 95% CI$_{\text{lower}} = -8.43$) were significantly related to PGSI.

Event-Related Analyses

Reels model

Fixations on the different regions of the screen varied by trial phase and outcome. The likelihood of fixating on the reels was lower during every outcome phase than it was during the reel spin (Table 3A, Figure 5).
Credit window model
Comparing winning outcome phases to reel spins, participants were less likely to fixate on the credit window during win feedback (OR = 0.58, Table 3B, Figure 5), but more likely during the ensuing spin initiation latency (OR = 1.46). During bonus feedback, fixations on the (then inactive) credit window were much less likely (OR < 0.01), but then were more likely during spin initiation latencies (OR = 4.32). On losses-disguised-as-wins, participants were less likely to fixate on the credit window during both feedback (OR = 0.32) and spin initiation latency (OR = 0.78).

Win window model
Comparing winning outcomes to reel spins, participants were more likely to look at the win window during both feedback (OR = 1.27, Table 3C, Figure 5) and spin initiation latency (OR = 6.56). For losses-disguised-as-wins, fixations were less likely during feedback (OR = 0.30), but more likely during spin initiation latency (OR = 1.99). During spin initiation latencies for bonuses, fixations on the win window were more likely (OR = 7.83).

Immersion interactions
Self-reported immersion interacted significantly with some outcomes in the win window and reels models. Higher-immersion participants were less likely to fixate on the reels during losses (OR = 1.42, Table 3A, Figure 5), and feedback for losses-disguised-as-wins (OR = 1.89), as well as spin initiation latencies for wins (OR = 1.97) and losses-disguised-as-wins (OR = 1.77). Higher-immersion participants were less likely to fixate on the win window during bonus feedback (OR = 0.14, Table 3C), as well as spin initiation latencies for wins (OR = 0.66), and losses-disguised-as-wins (OR = 0.72).

Discussion
We described ‘zoning in’ and ‘zoning out’ as competing characterizations of slot machine immersion. We examined experienced gamblers’ natural gaze behaviour while using a genuine slot machine. The ratio of dwell time on the game’s credit window over dwell time on the reels was positively related to immersion. This finding corroborated, and was predicated upon, the same relationship observed in a convenience-sampled pilot study (see Supplementary Materials S1). Notably the replicated effect was somewhat smaller, though still statistically significant. Thus, immersed participants were relatively more concerned with financial ‘performance’ related information and less concerned with the game’s appealing animations. We tested relationships between immersion and the ratio of fixations per minute on the credit window over the reels, and with problem gambling severity, but we did not find support for these additional hypotheses.
In exploratory analyses, the total number of saccades explained 15% of the variation in immersion scores, but was not associated with saccade amplitude. Thus, immersed gamblers differed in the amount they looked back and forth, but this did not depend on the exact pattern in which saccades occurred. Since less than 1% of dwell time was spent off-screen, we argue that immersed participants were more thorough in their inspection of the game screen. GRCS subscales indicated higher levels of illusory and predictive control in more-immersed participants. Thus, belief in one’s control over gambling outcomes may be elevated in gamblers who experience immersion.

These results strongly support a ‘zoned in’ interpretation of slot machine immersion that entails persistent interest in task performance. In the ‘zoned in’ model, immersion is a potential motivator – but not the sole motivator – of continued slot machine use among immersed individuals. We associated immersion with a focus on monetary outcomes, increased inspection of the game screen, and a stronger sense of control over gambling outcomes; all of which are hard to reconcile with a ‘zoned out’ or negative reinforcement-only model of slot machine immersion.

At the same time, not every result supported the ‘zoned in’ model. Event-related analyses revealed significant interactions between immersion and fixating on the game’s reels and win window. Although immersed gamblers were less likely to fixate on the reels during some outcomes, this was not coupled with a significant increase in fixations at the credit or win windows. Arguably, these interactions could be more consistent with a general disengagement from the game predicted by the ‘zoned out’ model. However, these exploratory analyses were not consistent across outcome types, and further study is needed to establish reliability.

Several limitations are of note. Our laboratory environment was quiet, minimally distracting, and our protocol required gamblers to use a specific bet strategy (Supplementary Materials S2). Although we selected a popular strategy (maximum paylines, minimum credits; 42,43), it is likely not the preferred bet style for all gamblers. Both factors reduce ecological validity compared to gambling in real venues. We declined to test high-risk problem gamblers, as participant payment ensured the gambling session would have a positive expected value, producing an unrealistically-favourable gambling experience. As we sampled exclusively from craigslist (44), and excluded high-risk problem gamblers, our results may not generalize to eye movements or immersion for clinical populations (45).

Our instruments were subject to important limitations as well. The psychometric properties of our immersion questionnaire are not well understood. The scale has not been rigorously validated for internal or external validity. Additionally, we selected a small number of eye movement metrics we believed would be informative. Measures such as pupillometry may alter our interpretation of slot machine immersion.

Irrespective of immersion, our event-related analyses found interesting eye movement patterns across different phases of slot machine spins. The likelihood of fixating on the win window before starting the next spin (i.e. during the spin initiation latency) increased after wins, bonuses and losses-disguised-as-wins, but not losses (Figure 5). Fixations on the credit window, however,
were more likely after wins and bonuses, but less likely after losses and losses-disguised-as-wins. Attention to the win window could contribute to the often-reported confusion between losses-disguised-as-wins and true wins (46). Notably, the relative infrequency of bonus feature outcomes prevented us from bootstrapping their confidence intervals, and may have also impacted the reliability of their odds ratios. Replication is especially important for these analyses.

These trends raise useful implications for responsible gambling messaging. On-screen pop-ups appear to be somewhat effective in reducing time on device (47–50). Stewart and Wohl (51) found that pop-up reminder messages improved spend-limit adherence. In real-world settings, however, the effect may be smaller (52), and may diminish with repeated exposure (53,54). Careful tailoring of message presentation could enhance these tools’ effectiveness: eye tracking results could be used to optimise on-screen message delivery both spatially (by AOI) and temporally (by phase or outcome) to coincide with gamblers’ attention. We found that fixations often increased at the credit and win windows in the spin initiation latency following wins, losses-disguised-as-wins, and bonuses. Messages presented there and then have the potential to garner greater engagement and resist habituation.

More broadly, these results speak to the conceptualization of immersion as a robust correlate of problem gambling. For problem gamblers, their families, clinicians, and venue staff, approaching gambling immersion as just one harmful example on a spectrum of immersive activities (including hobbies, playing sports, etc.), may be more productive for research and less stigmatizing than an approach that treats immersion as uniquely mollifying and solely achievable through gambling. To that end, we recommend adopting the terms ‘immersion’ or ‘flow’ (5) to describe the experience.

Note: Reported confidence intervals have been bootstrapped with 5000 iterations, except where denoted by ^A. OR = Odds Ratio, LDW = losses disguised as wins, SIL = Spin Initiation Latency, $R^2_N$ = Nagelkerke's Coefficient of Determination. Non-significant interaction terms were backward-eliminated from the models in descending order of significance.
Supplementary Materials

S1. Pilot Study and Pre-Registration

A convenience-sampled pilot study was conducted to direct the hypotheses of this experiment. The inclusion and exclusion criteria were identical to the follow-up study, except that we did not require participants to report past-year slot machine use. Thirty-three participants were recruited, though six (18.18%) were excluded due to incomplete data or equipment failure. The pilot sample thus consisted of 27 individuals (median age = 24, range = 19 – 67, 9 males, 18 females). Pilot participants did not complete the Gambling-Related Cognitions Scale (GRCS), the Depression Anxiety and Stress Scale (DASS), or some parts of the Canadian Problem Gambling Index. Procedures were otherwise identical to the main experiment.

In general, pilot participants reported few problem gambling symptoms: 19 (70.37%) gave a Problem Gambling Severity Index (PGSI) score of 0, five (18.52%) scored 1–2, and three (11.11%) scored 3–7. The median ASRS score was 9 (range = 4 – 17). The median immersion score was 0.86 out of 4 (range = 0.14 – 2.71). The median test session ended with $26.40 (range = $0 – $137.15) remaining of the initial $40 endowment. For the 8 (29.63%) participants who ran out of credit before 20 minutes of gambling had been recorded, the median session lasted 15.58 minutes (range = 12.74 – 20).

Eye movements to the credit window AOI were negatively correlated with ASRS (dwell time: $\beta$ = -0.47, $t(25)$ = -2.36, $p = .027$, $R^2 = .18$, 95% CI [-.88, -.16]; fixations: $\beta = -0.80$, $t(25)$ = -2.34, $p = .027$, $R^2 = .18$, 95% CI [-1.50, -.32]). These relationships were not mirrored with significant positive relationships at the reels AOI (dwell time: $\beta = -0.14$, $t(25) = -0.26$, $p = .797$, $R^2 < .01$, 95% CI [-1.18, 1.19]; fixations: $\beta = 0.15$, $t(25) = 0.10$, $p = .923$, $R^2 < .01$, 95% CI [-2.72, 3.27]). If replicated in the main experiment, these trends could impact our ability to interpret hypotheses concerning immersion and visual attention.

Pilot participants spent 71.9% of the task looking at the reels (SD = 8.30; see supplementary table S1), but often looked at other game features as well. 5.6% (SD = 3.50) of task time was spent looking at the credit window, 3.1% (SD = 1.84) at the win window, and only 0.9% (SD 1.08) on anything off-screen.

**INSERT TABLE S1 NEAR HERE**

There was a significant positive relationship between immersion and dwell time at the credit window AOI ($\beta = 2.06$, $t(25) = 2.19$, $p = .038$, $R^2 = .16$, 95% CI [-0.43, 4.66]), as well as a significant negative relationship between immersion and dwell time at the reels AOI ($\beta = -5.23$, $t(25) = -2.38$, $p = .025$, $R^2 = .18$, 95% CI [-9.38, 1.19]). This relationship, reflecting a shift in attention from the reels to the credit information, could be captured singularly as a correlation between immersion and the ratio of dwell time to the credit window AOI over the reels AOI ($\beta = 0.04$, $t(25) = 2.62$, $p = .015$, $R^2 = .22$, 95% CI [.0004, .09]). For visual fixations, there was a positive correlation between self-reported immersion and fixations at the credit window AOI ($\beta = 3.73$, $t(25) = 2.34$, $p = .028$, $R^2 = .18$, 95% CI [-0.50, 8.51]), but no significant relationship for the reels AOI ($\beta = -9.04$, $t(25) = -1.30$, $p = .205$, $R^2 = .06$, 95% CI [-20.19, 3.29]). Nevertheless,
the ratio measure (credit window AOI : reels AOI) was also significantly correlated with immersion ($\beta = 0.05$, $t(25) = 2.71$, $p = .012$, $R^2 = .23$, 95% CI [-0.002, 0.10]).

The main experiment sought to test the reliability of these relationships, in a larger sample composed of experienced gamblers. Sample size was based on power calculations using the effect size for the correlation between immersion and the ratio of dwell time to the credit window relative to the reels AOI (one-tailed). For the primary hypothesis, tests on ratios were favoured to mitigate type-1 error rate. We pre-registered the hypotheses and methods on aspredicted.org (https://aspredicted.org/k4ty9.pdf).

S2. Supplementary Methods

Questionnaires

After providing written consent, participants completed the Problem Gambling Severity Index (1), a 9-item scale that probes symptoms of problem gambling in the past year. A score of 8 or higher indicates high risk for problem gambling, and such participants were excluded from the slot machine procedure. In our analyses, the PGSI was treated as a continuous measure.

Participants completed the Short-Form Adult Attention Deficit Hyperactivity Disorder (ADHD) Self-Report Scale (2). The ASRS contains six items and probes adult ADHD symptomatology over the past six months. Responses were given on a 5-point Likert scale ranging from “Never (0)” to “Very often (4).” Items were summed at equal weight for scoring (see: 3). Several studies have linked adult ADHD and problem gambling (4–6).

The Gambling-Related Cognitions Scale (GRCS; 7) includes 23 items grouped into five factors that probe gamblers’ beliefs: interpretive bias (e.g. “relating my winnings to my skill and ability makes me continue gambling”), illusion of control (e.g. “specific numbers and colours can help increase my chances of winning”), predictive control (e.g. “I have some control over predicting my gambling wins”), gambling expectancies (e.g. “having a gamble helps reduce tension and stress”), and perceived inability to stop gambling (e.g. “I will never be able to stop gambling”). Responses were given on a 7-point Likert scale ranging from “Strongly disagree” to “Strongly agree.” Six participants failed to provide a response to a single item on this scale. The missing items were half-mean imputed using the affected subscales, following the recommendations of Bell and colleagues (8).

The Depression Anxiety and Stress Scale short-form (DASS; contains 21 items probing past-week experiences. Responses were scored on a 4-point Likert scale ranging from “Did not apply to me at all (0)” to “Applied to me very much, or most of the time (3).” Mood disorders are comorbid with problem gambling and have been linked to slot machine immersion (9,10). One participant was missing a single item. This cell was half-mean imputed using the mean of the affected subscale.

The Canadian Problem Gambling Index (1) includes an expansive list of gambling activities, and asks respondents to indicate how often they participated in each over the past year. Responses were scored on an 8-point Likert scale ranging from “Never” to “Daily.” It was used to verify the
consistency of participants’ self-reported slot machine use over the past year. Two participants were thus excluded.

Slot Machine Procedure

The slot machine session was carried out in our laboratory, which houses four genuine slot machines, balancing the ecological validity of real slot machines with the situational control afforded by a laboratory environment (11,12). Participants were endowed $40 to play “Buffalo Spirit” (Scientific Games Co., Las Vegas, NV). The game’s hold was 11% (i.e. at infinite spins, the game pays out $0.89 for every dollar wagered). Bets were constrained to $0.40, in order that participants were less likely to look away from the screen to re-configure their bet. A maximum-paylines (40), minimum-stake ($0.01) strategy was selected because it is popular among regular gamblers, and maximizes the reinforcement rate (13,14). Buffalo Spirit includes a ‘free spin’ bonus game that is triggered by the appearance of three specific symbols. During free spins, the game plays without user input, and winnings accrue in the Win window. Participants were not informed of the 20-minute duration but were instructed that any profits over the initial $40 endowment would be paid as a bonus, to a maximum of $20.

Apparatus

Natural gaze behaviour was recorded in real-time from both eyes using mobile eye tracking glasses (SMI, Teltow, Germany). Data were recorded at 60 Hz to a Samsung Galaxy Note 4 affixed to the back of the participant’s seat (Figure 1a). The glasses were 3-point calibrated using the top left, top right, and bottom left symbols on the slot machine screen (Figure 1b). Participants were allowed to seat themselves at a comfortable distance from the slot machine. Since SMI Eye Tracking Glasses preclude the use of prescription glasses, some participants selected approximate corrective lenses from the SMI corrective lens kit.

In order to derive the time series of slot machine events, we recorded and analyzed the slot machine screen during each session. The screen was duplicated using an HDMI Splitter (OREI, Skokie, IL), and passed via AV.IO Video Grabber (Epiphan, Palo Alto, CA) to a video capture computer running Debut 3.01 recording software at 60Hz (NCH, Greenwood Village, CO). These videos were processed using an image recognition program built in Python 2.7 using OpenCV2 (Intel, Santa Clara, CA). The output was a time series of game events for each participant.

Fixed-Effects Models

Dwell time data was converted into a binary format such that all non-zero values were converted to 1. These models thus reflect whether or not a fixation was recorded in a given AOI during a given trial phase (i.e. reel spin, feedback or spin initiation latency). Separate fixed-effects logistic regressions were carried out on the reels, credit window and win window. In a fixed-effects model, each subject is treated as their own control, and model estimates reflect increases or decreases in the likelihood that a given AOI is fixated-on during a given trial phase. With this approach, if a participant does not experience a particular outcome type (e.g. a free spin bonus), they do not contribute to the relevant estimate. In this way, there is no need to impute missing
data or exclude participants. Predictor variables were introduced in the following three steps: 1) subject, trial number and outcome phase duration, 2) outcome type and phase (reel spins were the reference category), and 3) interactions between significant predictors in stage 2 with immersion. After stage 3, interaction terms were backward-eliminated in descending order of significance until all non-significant interactions were removed from the model estimates. Odds ratios were computed. Models were assessed for multicollinearity and violations of linearity (15). The duration of trial phases appeared to show evidence of linear, quadratic, and cubic trends for certain models. Non-linear trends were not included in the model as they were not expected or clearly explicable, and their inclusion could thus capitalize on error variance in the model. Standardized residuals were calculated and plotted against the predictor variables. No relationships were apparent. Analysis scripts and all relevant data are available online.

S3. Supplementary Results

Self-report measures. The median ASRS score was 10 out of 24 (range = 0 – 17). The median scores for the depression, anxiety and stress subscales were 6 (range = 0 – 32), 4 (range = 0 – 30) and 10 (range = 0 – 36), respectively. PGSI was significantly related to ASRS (β = 0.70, t(51) = 2.27, p = .028, R² = .09, 95% CI [0.06, 1.25]), DASS subscales for anxiety (β = 1.78, t(51) = 4.11, p < .001, R² = .25, 95% CI [0.78, 3.02]), and stress (β = 1.62, t(51) = 2.81, p = .007, R² = .13, 95% CI [0.34, 3.22]), but not depression (β = 0.81, t(51) = 1.29, p = .201, R² = .03, 95% CI [-0.38, 2.50]). DASS depression was not associated with immersion (β = 2.13, t(51) = 1.14, p = .260, R² = .02, 95% CI [-1.24, 5.65]). When PGSI was included as a covariate, neither anxiety (β = 1.01, t(50) = 0.73, p = .468, R²artial = .01, 95% CI [-1.94, 4.24]) nor stress (β = 3.56, t(50) = 2.01, p = .050, R²artial = .07, 95% CI [-0.97, 6.94]) were associated with immersion.

PGSI score was positively correlated with GRCS subscales for illusion of control (β = 0.24, t(51) = 3.04, p = .004, R² = .15, 95% CI [0.05, 0.49]), predictive control (β = 0.23, t(51) = 2.57, p = .013, R² = .11, 95% CI [0.03, 0.39]) and interpretive bias (β = 0.29, t(51) = 3.16, p = .003, R² = .16, 95% CI [0.09, 0.49]), but not gambling expectancies (β = 0.18, t(51) = 1.94, p = .058, R² = .07, 95% CI [-0.02, 0.35]) or inability to stop gambling (β = 0.10, t(51) = 1.99, p = .052, R² = .07, 95% CI [-0.03, 0.23]). When we examined relationships between GRCS subscales and immersion, we included PGSI as a covariate. Immersion was significantly related to GRCS subscales for illusionary control (β = 0.73, t(50) = 3.18, p = .003, R²artial = .17, 95% CI [0.30, 1.23]), predictive control (β = 0.65, t(50) = 2.47, p = .017, R²artial = .11, 95% CI [0.10, 1.20]), gambling expectancies (β = 0.66, t(50) = 2.39, p = .021, R²artial = .10, 95% CI [0.06, 1.33]), and interpretive bias (β = 0.79, t(50) = 2.91, p = .005, R²artial = .14, 95% CI [0.22, 1.34]), but not perceived inability to stop gambling (β = 0.06, t(50) = 0.42, p = .679, R²artial < .01, 95% CI [-0.27, 0.38]).

Despite evidence in the pilot sample of a relationship between adult ADHD and fixations and dwell time on the slot machine credit window, secondary hypotheses concerning the relationships between ASRS and dwell time on the credit window (β = -0.05, t(51) = -0.50, p = .62, R² < .01, 95% CI [-0.21, 0.12]), dwell time on the reels (β = 0.31, t(51) = 0.98, p = .33, R² =
.02, 95% CI [-0.26, 0.92]), fixations on the credit window (β = -0.12, t(51) = -0.76, p = .450, R² = .01, 95% CI [-0.42, 0.20]), and fixations on the reels (β = -0.39, t(51) = -0.59, p = .559, R² = .01, 95% CI [-1.85, 1.00]), were not supported.

Behavioural measures. PGSI score was not significantly correlated with the number of saccades per minute during the slot machine task (β = 0.75, t(51) = 0.45, p = .653, R² < .01, 95% CI [-2.64, 4.15]). The number of blinks per minute of the session was not correlated with PGSI (β = -1.05, t(51) = -1.45, p = .152, R² = .04, 95% CI [-2.55, 0.07]), or immersion (β = 1.28, t(51) = 0.59, p = .558, R² = .01, 95% CI [-2.88, 5.40]).
